

Neurobiological Risk Factors for Suicide

Insights from Brain Imaging

Elizabeth T. Cox Lippard, PhD, Jennifer A.Y. Johnston, MA, Hilary P. Blumberg, MD

Context: This article reviews neuroimaging studies on neural circuitry associated with suicide-related thoughts and behaviors to identify areas of convergence in findings. Gaps in the literature for which additional research is needed are identified.

Evidence acquisition: A PubMed search was conducted and articles published before March 2014 were reviewed that compared individuals who made suicide attempts to those with similar diagnoses who had not made attempts or to healthy comparison subjects. Articles on adults with suicidal ideation and adolescents who had made attempts, or with suicidal ideation, were also included. Reviewed imaging modalities included structural magnetic resonance imaging, diffusion tensor imaging, single photon emission computed tomography, positron emission tomography, and functional magnetic resonance imaging.

Evidence synthesis: Although many studies include small samples, and subject characteristics and imaging methods vary across studies, there were convergent findings involving the structure and function of frontal neural systems and the serotonergic system.

Conclusions: These initial neuroimaging studies of suicide behavior have provided promising results. Future neuroimaging efforts could be strengthened by more strategic use of common data elements and a focus on suicide risk trajectories. At-risk subgroups defined by biopsychosocial risk factors and multidimensional assessment of suicidal thoughts and behaviors may provide a clearer picture of the neural circuitry associated with risk status—both current and lifetime. Also needed are studies investigating neural changes associated with interventions that are effective in risk reduction. Introduction

This paper reviews neuroimaging studies on neural circuitry associated with suicide-related thoughts and behaviors in an effort to recommend next research steps. Multiple neuroimaging methods have been employed to investigate the neural circuitry of suicide-related thoughts and behaviors. These include techniques to study brain structure, including structural magnetic resonance imaging (sMRI) for gray matter (GM) and white matter (WM) morphology and WM hyperintensities (WMHs, bright signals on T2-weighted MRIs), and diffusion tensor imaging (DTI) for structural integrity of WM connections. Several functional neuroimaging methods

(single photon emission computed tomography [SPECT]; positron emission tomography [PET]; and functional magnetic resonance imaging [fMRI]) have been used to study regional brain activity, functional connectivity, and neurotransmitter function.

Evidence Acquisition

A search was performed in PubMed for original research manuscripts written in English before March 2014. Combinations of the term *suicide* with terms *structural magnetic resonance imaging*, *functional magnetic resonance imaging*, *positron emission tomography*, *single-photon emission computed tomography*, *diffusion tensor imaging*, *gray matter*, or *white matter* were used. Fifty-seven pertinent articles that directly investigated the relationship between aspects of suicide behavior (i.e., attempt history, lethality, and suicide ideation) and neuroimaging findings were chosen and evaluated in a non-quantitative manner.

Evidence Synthesis

In the majority of studies, attempters and non-attempters with a particular diagnosis were compared to each other,

and sometimes to a healthy control (HC) group (summarized in Table 1). The most commonly studied diagnoses were major depressive disorder (MDD) and bipolar disorder (BD), followed by schizophrenia; borderline personality disorder (BPD); traumatic brain injury (TBI); and epilepsy. Studies of adults with attempts are discussed first, followed by adults with ideation. We then summarize findings in older adults and adolescents.

Structural Magnetic Resonance Imaging

Structural magnetic resonance imaging of gray and white matter morphology. Structural imaging has been the method most used in suicide research. Studies using sMRI converge in showing orbitofrontal cortex (OFC) GM decreases in attempters with MDD,¹ BD,² schizophrenia,³ and BPD,⁴ and amygdala GM increases in MDD¹ and schizophrenia.⁵ The OFC and amygdala are highly interconnected regions, important in regulating emotions and impulses, suggesting that frontotemporal OFC–amygdala structural abnormalities may contribute to emotion and impulse dysregulation associated with attempts. In BPD, OFC decreases were of larger magnitude in attempters with higher medical lethality.⁴

GM findings have been reported in other frontal system components in attempters with schizophrenia,^{3,6} BPD,⁴ BD,² and MDD.^{7–9} These include dorsal frontal regions, insula, thalamus, and basal ganglia, implicating more widely distributed frontotemporal anterior connection sites. A study of the cerebellum yielded negative findings.¹⁰

Studies using sMRI show abnormal frontotemporal WM connections. A study of schizophrenia showed increased inferior frontal WM volume in attempters with self-directed aggression.¹¹ The sMRI studies also show altered interhemispheric connections. Smaller genu corpus callosum (CC) volume in BD attempters was associated with increased Barratt Impulsivity Scale scores.¹² These studies suggest that WM abnormalities contribute to self-aggression and impulse dyscontrol of suicidal behavior.

White matter hyperintensities. Increased WMH prevalence has been reported in young/mid-adult MDD and BD attempters,^{13–15} and in older adults and children. Etiologies contributing to WMHs may include cellular loss, ischemia, perivascular space dilation, ependymal loss, and vascular-related demyelination.^{16–18}

Diffusion tensor imaging. The main reported DTI measure is fractional anisotropy (FA), which reflects the directional coherence of diffusion within WM bundles, their architecture, or structural integrity. Decreased frontal FA in BD and MDD attempters has been found.^{19–21} In BD, orbitofrontal FA decreases were associated with

impulsivity. In MDD attempters, disruptions were found in frontal cortex–basal ganglia WM connections that are important in behavioral control.^{20,22} In veterans with TBI and attempt history, FA increases in frontal WM projections were associated with impulsivity.²³ These DTI data further support the contributions of anterior WM abnormalities to impulsive suicide behavior.

Functional Neuroimaging

Single photon emission computed tomography and positron emission tomography. A SPECT study showed blunted prefrontal cortex (PFC) regional cerebral blood flow (rCBF) responses during word generation in attempters,²⁴ consistent with the frontal findings described above. Lower frontal, insular, and caudate rCBF predicted attempts in a study with prospective assessment of suicide decedents.²⁵

A regional cerebral metabolic rate of glucose (rCMRglu) PET study reported OFC hypometabolism in BPD attempters.²⁶ Additionally, in rCMRglu PET studies, fenfluramine challenges have probed the serotonin (5-HT) system. Results indicated hypometabolism in right dorsolateral PFC in attempters and in association with ideation.²⁷ Ventral PFC hypometabolism differentiated between high-lethality and low-lethality attempters.²⁸ These studies suggest linkages between PFC response, 5-HT, suicide ideation, and attempt medical lethality, thus extending results of postmortem, cerebrospinal fluid, peripheral, and neuroendocrine challenge studies implicating 5-HT in suicide attempts and their lethality.

SPECT and PET neurotransmitter studies in attempters have focused on 5-HT and frontal systems. Findings include alterations in OFC 5-HT synthesis²⁹; 5-HT transporter (5-HTT) binding^{30–32}; associations among 5-HTT binding and SLC6A4 genetic variations³³; and basal ganglia volume⁹ and lower frontal 5HT-2a receptor binding.^{34,35} Associations have been reported between impulsivity and 5-HTT binding in whole brain, OFC, and other frontotemporal system components.^{36,37} Additionally, an association between lower frontal 5HT-2a receptor binding and hopelessness has been reported.³⁵ Genetic, postmortem, neuroendocrine, and peripheral studies also implicate noradrenergic and dopaminergic systems, and neurotrophic mechanisms, suggesting the need for their study.

Functional magnetic resonance imaging. The few reported fMRI studies of attempters are in MDD. One study of men showed elevated OFC responses to angry faces, suggesting that male MDD attempters have increased sensitivity to disapproval or threat.³⁸ Male attempters also showed decreased left OFC activation

Table 1. Neuroimaging studies of groups with suicide attempters

| Authors and year | Group with history of suicide attempts | Group(s) without attempts | Methods | Findings |
|--------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------|---------------------------|-------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Structural magnetic resonance imaging studies of gray matter and white matter | | | | |
| Aguilar et al. 2008 ³ | 13 males with SCZ, mean age 37 years | 24 DCs | VBM of GM density | ↓ OFC and superior temporal GM density, relative to DCs |
| Baldacara et al. 2011 ¹⁰ | 20 with BD, mean age 40 years | 20 DCs, 22 HCs | VBM of GM and WM brain volume; ROI volume | No significant differences in total brain volume or cerebellar volume |
| Benedetti et al. 2011 ² | 19 with BD, mean age 45 years | 38 DCs | VBM of GM volume | ↓ GM volume in DLPFC, OFC, ACC, superior temporal, parietal and occipital cortex and ↑ in bilateral superior temporal gyrus, relative to DCs. With lithium ↑ GM volume in same regions (DLPFC, OFC, ACC, superior temporal, parietal, and occipital cortex) and ↓ in bilateral superior temporal gyrus |
| Giakoumatos et al. 2013 ⁶ | 148 with SCZ, SZA or BDP, mean age 36 years | 341 DCs, 262 HCs | VBM of GM volume | ↓ GM volume in bilateral superior/middle frontal, and inferior/superior temporal regions, left superior parietal and supramarginal regions, and right insula and thalamus, relative to DCs and HCs. High (versus low) lethality showed ↓ in left lingual area and right cuneus |
| Matsuo et al. 2010 ¹² | 10 females with BD, mean age 36 years | 10 DCs, 27 HCs | ROI area | Anterior CC genu area associated with impulsivity |
| Monkul et al. 2007 ¹ | 7 females with MDD, mean age 31 years | 10 DCs, 17 HCs | ROI volume | ↓ OFC GM, relative to HCs. ↓ amygdala volumes, relative to DCs |
| Rüsch et al. 2008 ¹¹ | 10 with SCZ, mean age 30 years | 45 DCs, 55 HCs | VBM of GM and WM | ↑ bilateral inferior frontal WM volume, relative to DCs. In SCZ ↑ inferior frontal related to self-aggression |
| Soloff et al. 2012 ⁴ | 44 with BPD (25 high lethality), mean age 30 years | 24 DCs, 52 HCs | ROI volume | ↓ insula GM, relative to DCs. ↓ in high lethality attempters in OFC, middle/superior temporal gyrus, insula, fusiform gyrus, lingual gyrus, and parahippocampal gyrus |
| Spoletini et al. 2011 ⁵ | 14 with SCZ, mean age 43 years | 36 DCs, 50 HCs | ROI volume | ↑ amygdala, relative to DCs and HCs. In the SCZ group, ↑ amygdala volume associated with self-aggression |
| Vang et al. 2010 ⁹ | 7 (4 with MDD, 2 AD), mean age 38 years | 6 HCs | ¹²³ I-β-CIT methods to separate 5-HTT and DAT uptake in ROIs | ↓ GP and caudate, relative to HCs and correlated with 5-HTT binding. In attempters, GP volumes inversely correlated with non-impulsive temperament |
| Wagner et al. 2011 ⁷ | 15 with MDD (10 with suicide behavior, 5 with first-degree relatives with suicidal behavior), mean age 41 years | 15 DCs, 30 HCs | VBM of GM density | ↓ inferior frontal cortex, ACC, caudate, amygdala/hippocampus formation, relative to HCs. ↓ ACC and caudate, relative to DCs |
| Wagner et al. 2012 ⁸ | Same sample as in Wagner et al. 2011 above | 15 DCs, 30 HCs | Cortical thickness | ↓ ventrolateral PFC, DLPFC, and ACC, relative to DCs and HCs |

associated with risky gambling task choices.³⁹ When fMRI was performed during a motor task by attempters,⁴⁰ altered activation and functional connectivity within and between regions in a corticostriatal network were shown. In one of the few studies examining internal states and thoughts of suicide, fMRI showed frontal decreases during autobiographic recall of mental pain associated with previous attempts, and frontotemporal increases during recall of suicide actions.⁴¹

Suicidal Ideation

Study of suicidal ideation is important for understanding the development of risk for attempts. Of the few structural studies of suicide ideation, non-attempters with ideation did not show the WM abnormalities noted in attempters, although one DTI study of ideation in veterans with TBI did show FA reductions in the cingulum, a structure important in emotional memory.^{13,42} The absence of frontal WM findings in non-attempters with ideation suggests that these findings are more closely associated with suicidal acts and possibly the more impulsive aspects of some attempts. It is possible that WM disruptions are a consequence of suicide attempt methods that could affect the brain, for example, as a consequence of hypoxia, although some studies have noted similar findings in attempters who did not use such methods.¹³

Brain dysfunction has shown some consistencies among ideators and attempters. Performance of a motor activation task by BDII ideators showed frontostriatal findings similar to those in attempters.⁴³ In another fMRI study of combat-exposed war veterans performing a stop task,⁴⁴ ideation was associated with higher frontal error-related activation.

Older Adult Attempters

Biopsychosocial features of aging may confer neurobiological risk for suicide. WMHs and other WM pathology may be more prevalent in older adult attempters.^{45,46} Early findings of increased WMHs in older adults suggested pathologic processes (e.g., vascular disease) more prevalent in older adults.^{16–18} However, recent studies reporting similarly increased WMHs in younger adults and adolescents suggest that alternative mechanisms may underlie WMHs. Although underlying mechanisms may differ, findings in adults aged over 60 years show consistencies with findings in younger adults. For example, older adult MDD attempters also show decreased basal ganglia GM and relationships to reward processing and behavioral control.^{47,48} CC WM decreases have been reported in older adult attempters with mood and anxiety disorders, although in older

attempters these were in the posterior third,⁴⁹ implicating more involvement of emotion and memory processes. Older adult attempters also show decreases in ventromedial PFC responses to rewards, associated with impulsivity.⁵⁰ In light of few comparison studies of older to younger adults, more research is needed on similarities and distinctions between the pathophysiology and neural circuitry underlying suicide behavior across life span stages.

Suicide Attempts and Ideation in Children and Adolescents

Neuroimaging research with adolescents is important, as adolescence is a critical period in suicide behavior development. Structural imaging studies of children and adolescents—with epilepsy,⁵¹ as psychiatric inpatients,^{52,53} or outpatients with BPD and MDD⁵⁴—show some consistencies with studies in adults, suggesting these abnormalities may relate to development of suicide-related thoughts and behaviors. Findings include smaller OFC WM in young ideators,⁵¹ more prevalent WMHs in MDD young attempters,^{52,53} and smaller anterior cingulate GM and WM volumes in adolescents with more suicide attempts.⁵⁴

An fMRI study in MDD adolescents showed increased responses to angry faces in frontal circuitry,⁵⁵ similar to that found in adults.³⁸ However, MDD adolescent attempters did not show differential neural responses during response inhibition on a go-no-go task or decision making in the context of risk.^{56,57} These findings suggest increased sensitivity in frontal systems involved in negative emotion processing may characterize adolescent attempters.

Recommendations for Future Research

Despite highly varied methods and small samples, the structural and functional neuroimaging findings converge in implicating frontal neural systems and serotonergic functioning as central in suicide behavior, consistent with studies using non-imaging approaches. As neuroimaging studies are expensive, scanning time limited, and at-risk patients difficult to retain in studies, future neuroimaging efforts could benefit from more strategic approaches.

Common Data Elements

As illustrated above and in Table 1, there is substantial variation in age, gender, psychopathology, imaging methods and regions studied, activation paradigms, and behavioral constructs probed. Studies vary in defining “attempters.” Although neuropsychological constructs related to emotion and impulse regulation have been

most studied, definitions of these constructs and methods to assess them have varied. Efforts to use common definitions of suicide behavior and neuropsychological processes, and methods to assess them, could lead to better synthesis across studies. Similarly, calibration of imaging hardware and analytic techniques will be needed. In efforts to link brain imaging to age, gender, and genetic, postmortem, neurotransmitter, neurotrophic, hormonal, and environmental findings and to elucidate commonalities and distinctions between suicide behavior in different psychiatric disorders, the use of common data elements could make cross-study comparisons more likely and of greater value. Future studies may benefit from including new analytic approaches, such as computer learning algorithms comparing imaging data on cases and controls, in larger samples.

However, this field is in its early stages and there is risk to premature focus. Although initial work has focused on frontal systems and related behavioral constructs such as impulsivity and 5-HT, and these have shown importance in attempters, the field is also in need of novel approaches to study other aspects of suicide. For example, few studies have focused on ideation. There is a critical need for investigators who develop ideation-related constructs and innovative methods to probe them.

Suicide Risk and Trajectories

Two major gaps in the study of individuals at risk for suicide over time were identified. First, longitudinal studies are critically needed of individuals at risk, especially beginning in youth, to study biopsychosocial factors and neural trajectories both associated with and not with future attempts. These could reveal predictors and trajectories associated with future attempts, as well as with resilience in individuals who do not make attempts. Second, neuroimaging studies before and after pharmacologic and behavioral interventions could be instrumental in promoting understanding of therapeutic mechanisms in treatment response.

Conclusions

It is an important time for research in the neural circuitry of suicide-related thoughts and behaviors. Important groundwork has been laid by initial neuroimaging studies. Despite the small size and heterogeneity of these studies, some convergent findings provide a promising start. The identification of associations among genetic and molecular mechanisms, brain circuitry, ideation, and behavior could be instrumental in identifying targets for prevention. Future neuroimaging efforts could be leveraged by more strategic use of common data elements and efforts to fill gaps in understanding of suicide risk trajectories. At-risk

subgroups defined by risk experiences and psychopathology subtypes may provide a clearer picture of the neural changes associated with suicide risk status—both current and lifetime. Expanding research efforts that examine structural and functional changes related to intervention responses can inform risk and prevention models.

Publication of this article was supported by the Centers for Disease Control and Prevention, the National Institutes of Health Office of Behavioral and Social Sciences, and the National Institutes of Health Office of Disease Prevention. This support was provided as part of the National Institute of Mental Health-staffed Research Prioritization Task Force of the National Action Alliance for Suicide Prevention.

Funding was received by HPB from the NIH (Grant Nos.
